PARA*: Parallel Anytime Repairing A*

AAAI 2015 Submission X

Abstract

PARA* is an anytime parallel heuristic search algorithm based on ARA* and PA*SE, which are in turn based on A*.

Fancy Stuff

Algorithm 1 bound(s)

```
\begin{array}{l} g_{front} \coloneqq \infty \\ s' \coloneqq \text{first node in } OPEN \cup BE \\ g_{back} \coloneqq g(s) + f(s') - f(s) + (2\epsilon - w - 1)c_l \\ \textbf{while } g_{back} < g(s) \le g_{front} \textbf{do} \\ g_{front} \coloneqq \min(g_{front}, \ g_p(s') + \epsilon h(s', s)) \\ s' \coloneqq \text{node following } s' \text{ in } OPEN \cup BE \\ g_{back} \coloneqq g(s) + f(s') - f(s) + (2\epsilon - w - 1)c_l \\ \textbf{end while} \\ \textbf{return } \min(g_{front}, \ g_{back}) \end{array}
```

Keys are always computed by $f(s) = g(s) + wh(s, s_{goal})$, and we assume all edge costs are bounded below by c_l . h must be consistent: $h(s,s') \leq c(s,s')$ and $h(s,s') \leq h(s,s'') + h(s'',s')$ for all s,s',s''. For most applications, we recommend using $w = \epsilon$. However, our analysis will show that using small w yields strong parallelism guarantees. All operations on the data structures OPEN, BE, CLOSED, FROZEN are assumed to be atomic, i.e. they are implicitly preceded and succeeded by synchronous locks and unlocks to the data structure, respectively. ϵ decreases between iterations of the main() loop. v(s) is included to aid the analysis but is never used in the algorithm. In main(), the loops involving all $s \notin OPEN$ are computed lazily when those states are first encountered.

Lemma 1. At all times, the following invariants hold:

- $OPEN \cap CLOSED = \emptyset$
- $BE \cup FROZEN \subset CLOSED$
- $s \in OPEN \cup BE \cup FROZEN \Rightarrow g(s) < v(s)$
- $s \notin OPEN \cup BE \cup FROZEN \Rightarrow g(s) = v(s)$
- $g(bp(s)) + c(bp(s), s) \le g(s) \le min_{s'} \{v(s') + c(s', s)\}$

Algorithm 2 expand(s)

```
for all s' \in successors(s) do
  LOCK s'
  if s' was not yet seen in this main() iteration then
     g_p(s') := \infty
     if s' has not been generated yet then
       q(s') := v(s') := \infty
     end if
  end if
  g_p(s') = \min(g_p(s'), g_{bound} + \epsilon c(s, s'))
  if g(s') > g(s) + c(s, s') then
     g(s') = g(s) + c(s, s')
     bp(s') = s
     if s' \in CLOSED then
       insert s' in FROZEN
       insert/update s' in OPEN with key f(s')
     end if
  end if
  UNLOCK s'
end for
```

Algorithm 3 PARA*

```
while g(s_{qoal}) > bound(s_{qoal}) do
  among s \in OPEN such that g(s) \leq bound(s), re-
  move one with the smallest f(s) and LOCK s
  if such an s does not exist then
    wait until OPEN or BE change
    continue
  end if
  g_{bound} := bound(s)
  v_{expand} := g(s)
  insert s into \hat{CLOSED}
  insert s into BE with key f(s)
  UNLOCK s
  expand(s)
  v(s) := v_{expand}
  remove s from BE
end while
```

Algorithm 4 main()

```
\begin{aligned} OPEN &:= BE := \emptyset \\ FROZEN &:= \{s_{start}\} \\ g(s_{start}) &:= 0 \\ \textbf{repeat} \\ &\text{choose } \epsilon \in [1, \infty] \text{ and } w \in [0, \epsilon] \\ OPEN &:= OPEN \cup FROZEN \text{ with keys } f(s) \\ CLOSED &:= FROZEN := \emptyset \\ \textbf{for all } s \in OPEN \textbf{ do} \\ g_p(s) &:= \epsilon g(s) \\ \textbf{end for} \\ \text{run PARA* on multiple threads in parallel} \\ \textbf{until path is good enough or planning time runs out} \end{aligned}
```

- Following $bp(\cdot)$ from s yields a path costing at most g(s)
- $s \neq s_{start} \Rightarrow g(s) + (\epsilon 1)c_l \leq g_p(s)$
- $s \in OPEN \cup CLOSED \Rightarrow g_p(s) \le \epsilon g(s)$
- $s \in OPEN \cup CLOSED$ iff we had g(s) < v(s) sometime during the current main() loop iteration

Proof. Induction on time.

Lemma 2. At all times, for all states $s, s' \neq s_{start}$:

$$g(s) + f(s') - f(s) + (2\epsilon - w - 1)c_l \le g_p(s') + \epsilon h(s', s).$$

Proof.

$$g(s) + f(s') - f(s) + (2\epsilon - w - 1)c_l$$

$$= g(s') + w(h(s', s_{goal}) - h(s, s_{goal})) + (2\epsilon - w - 1)c_l$$

$$\leq g(s') + wh(s', s) + (2\epsilon - w - 1)c_l$$

$$\leq g(s') + \epsilon h(s', s) + (w - \epsilon)c_l + (2\epsilon - w - 1)c_l$$

$$= g(s') + (\epsilon - 1)c_l + \epsilon h(s', s)$$

$$\leq g_n(s') + \epsilon h(s', s)$$

Lemma 3. For all states s, bound $(s) \le \min_{s' \in OPEN \cup BE} g_p(s') + \epsilon h(s', s)$. Furthermore, $g(s) \le bound(s)$ iff $g(s) \le \min_{s' \in OPEN \cup BE} g_p(s') + \epsilon h(s', s)$.

Proof. By construction, bound(s) is bounded above by $g_p(s') + \epsilon h(s',s)$ for states s' which are checked in the loop. As for the remaining states $s' \in OPEN \cup BE$, the algorithm ensures that $bound(s) \leq g(s) + f(s') - f(s) + (2\epsilon - w - 1)c_l$ for these by using a minimum representative. By Lemma 2, it follows that

$$bound(s) \le \min_{s' \in OPEN \cup BE} g_p(s') + \epsilon h(s', s).$$

To prove the second claim, note that the loop in bound(s) terminates under only two conditions. Either $g(s) > g_{front}$, in which case we have $g(s) > g_p(s') + \epsilon h(s',s) \geq bound(s)$ for the s' which began the final iteration; or $g(s) \leq g_{back}$, in which case $g(s) \leq bound(s)$ iff $g(s) \leq g_{front}$ iff $g(s) \leq g_p(s') + \epsilon h(s',s)$ for all $s' \in OPEN \cup BE$.

Theorem 1. For all $s \in OPEN \cup BE$, bound $(s) \le \epsilon g^*(s)$. Hence, for all $s \in CLOSED$, $g(s) \le v(s) \le \epsilon g^*(s)$.

Proof. We proceed by induction on the order in which states are expanded.

Let $\pi = \langle s_0, s_1, \dots, s_N \rangle$ be a minimum-cost path from $s_0 = s_{start}$ to $s_N = s \in OPEN \cup BE$ There are two cases to consider, depending on whether there exists $s_i \in \pi$ such that $s_i \in CLOSED \setminus BE$.

If so, choose the maximum such i. Since s_i was expanded and yet $s_{i+1} \notin CLOSED \setminus BE$, it follows that $s_{i+1} \in OPEN \cup BE$ and, by the induction hypothesis,

$$g_p(s_{i+1}) \le \epsilon g^*(s_i) + \epsilon c(s_i, s_{i+1}) = \epsilon g^*(s_{i+1})$$

One the other hand, suppose there is no $s_i \in CLOSED \setminus BE$. Choose the minimum i such that $s_i \in OPEN \cup BE$. Then $s_j \notin OPEN \cup CLOSED$ for all j < i, which by Lemma 1 implies $g(s_j) = v(s_j)$ and $g(s_i) = \sum_{j=1}^i c(s_{j-1}, s_j) = g^*(s_i)$. Therefore,

$$g_p(s_i) \le \epsilon g(s_i) = \epsilon g^*(s_i)$$

In either case, we found an $s' \in OPEN \cup BE$ such that

$$g_p(s') + \epsilon h(s', s) \le \epsilon (g^*(s') + c^*(s', s)) = \epsilon g^*(s).$$

Therefore, by Lemma 3,

$$bound(s) \le \min_{s' \in OPEN \cup BE} g_p(s') + \epsilon h(s', s) \le \epsilon g^*(s).$$

Corollary 1. At the end of a main() loop iteration, the path obtained by following the back-pointers $bp(\cdot)$ from s_{goal} to s_{start} is ϵ -suboptimal.

Proof. The termination condition of PARA* implies $g(s_{goal}) \leq bound(s_{goal})$. By construction, the path given by following back-pointers costs at most $g(s_{goal})$. The claim now follows from Theorem 1.

Performance Guarantees

Consider a simplified version of PARA* which ignores the loop in bound(s): we call it blind PARA*. In this case, no g_p values need be computed nor stored, and bound(s) is simply $g(s)+f_{min}-f(s)+(2\epsilon-w-1)c_l$ where f_{min} is the minimum f-value in $OPEN \cup BE$. Blind PARA* can only expand states which would be proved safe with zero iterations of the bound(s) loop in ordinary PARA*. Thus, all of the performance guarantees we prove for blind PARA* also hold for PARA*.

Theorem 2. If $w \le 1$, the parallel depth of blind PARA* is bounded above by

$$\min\left(\frac{\epsilon g^*(s_{goal})}{(1-w)c_l}, \frac{(\epsilon g^*(s_{goal}))^2}{(4\epsilon-2w-2)c_l^2}\right).$$

Proof. We prove the two bounds separately. For the first, note that if the lowest f-value is f_{min} , every state with f-value up to $f_{min} + (2\epsilon - w - 1)c_l$ can simultaneously be expanded. Since h is consistent, the successors' f-values is at least $f_{min} + (1 - w)c_l$. Therefore, the depth is at most

$$\frac{\epsilon g^*(s_{goal})}{(1-w)c_l}$$

For the other bound, notice that since f-values never decrease along paths, once the minimum f-value in OPEN surpasses f_{min} , from then on all nodes with f-value up to $f_{min} + (2\epsilon - w - 1)c_l$ are always safe to expand. And during each iteration of the simultaneous expansions, the g-value of all such nodes increases by at least c_l . Since g cannot exceed f, this continues for at most $(f_{min} + (2\epsilon - w - 1)c_l)/c_l = f_{min}/c_l + 2\epsilon - w - 1$ iterations, after which every node in OPEN has f-value $\geq f_{min} + (2\epsilon - w - 1)c_l$. Continuing this process until f_{min} exceeds $\epsilon g^*(s_{goal})$, a bound on the total iteration count is:

$$\begin{array}{ccc} 2\epsilon-w-1+2(2\epsilon-w-1)+3(2\epsilon-w-1)+\ldots+\\ \epsilon g^*(s_{goal})/c_l \approxeq (\epsilon g^*(s_{goal})/c_l)^2/(4\epsilon-2w-2). \end{array} \quad \Box$$

Edgewise Supobtimality

Let k(s) be the least number of edges used in a minimum-cost path to s and fix $\delta>0$. If g_{front} and g_{back} are each increased by 2δ , then by similar arguments to the proofs earlier in the paper, we find that, upon expanding $s, g(s) \leq \epsilon g^*(s) + \delta k(s)$.

Here's an extension inspired by (Klein and Subramanian 1997): suppose the mean edge cost c_m along the optimal path is known to be much greater than the lower bound c_l . In such a case, the bound in Theorem 2 scales poorly. To remedy the situation, we "grow" the small edges, effectively running PARA* with $c'_l = c_l + \delta$ and $c'(s, s') = \max(c(s, s'), c'_l)$.

Theorem 3. If the mean cost of the edges along the minimum-cost path to s is at least c_m , then upon expansion, $g(s) \le \epsilon(1 + \delta/c_m)g^*(s)$. Therefore, to get the same optimality factor as ϵ , we can set $\delta = (\epsilon - 1)c_m$.

Proof. We assumed $c_m \leq g^*(s)/k(s)$, so $k(s) \leq g^*(s)/c_m$. It follows from Lemma 1 that $g'(s) \leq \epsilon g'^*(s) \leq \epsilon (g^*(s) + \delta k(s)) \leq \epsilon (1 + \delta/c_m)g^*(s)$.

Corollary 2. If $w \le 1$, the parallel depth of blind PARA* can be improved to

$$\frac{\epsilon g^*(s_{goal})}{(1-w)(c_l+(\epsilon-1)c_m)}.$$
